JUNCTION-SIDE ILLUMINATED SILICON DETECTOR ARRAYS

STATEMENT REGARDING FEDERALLY SPONSORED RESEARCH OR DEVELOPMENT

FIELD OF THE INVENTION

10   The present invention relates to radiation detectors
and more specifically, to a structure of and a method for
fabricating pixelated silicon detector arrays and
photodetector arrays.

BACKGROUND OF THE INVENTION

15

Many applications can benefit from a development of
advanced pixelated silicon detector arrays with superior
characteristics for dark leakage current, quantum
efficiency, and production yields. One such application
20 involves silicon photodetector arrays that can be used to
construct gamma-ray cameras with very high resolution.

Highly pixelated silicon photodetector arrays coupled
to closely matched parallel piped CsI(Tl) scintillator
arrays are a known basis for solid state gamma-ray cameras
25 capable of imaging a wide variety of subjects ranging from
small animals in the laboratory to whole human bodies. One
example of silicon photodetector arrays for radiation
imaging is disclosed in U.S. Patent No. 5,773,829 entitled
"Radiation Imaging Detector," issued June 30, 1998 to
30 Iwanczyk and Patt, which is hereby incorporated by
reference in full.

Express Mail No. _Ei751147110S_

1

Large-sized solid state gamma-ray cameras employing such radiation imaging detectors typically require low cost and high-yield semiconductor photodetector array structures with superior performance and competitive prices compared to those of the existing clinical systems for Single Photon Emission Computed Tomography (SPECT) which utilize known vacuum Photomultiplier Tube (PMT) technologies.

Other broad applications including radiation hardened detector arrays for high-energy physics research, and new designs of avalanche imaging arrays (photodetectors with an internal gain) would also benefit from a development of low cost, high-yield detector array structures.

Typical silicon photodiode arrays with parallel signal readout are based on (p+)-(n)-(n+ structures constructed on high resistivity (0.1 - 10 k ohm-cm) silicon wafers. P+ contacts forming junctions in the n-type substrate are constructed in the form of a diode array. A common n+ contact forms an ohmic contact, and is used as an entrance window (light sensitive window).

Structures wherein the n+ (ohmic) contact is used as the entrance window for light, x-rays, gamma rays, or particles, and in which the p+ (junction) contacts are used as the readout are referred to as back-side illuminated photodiodes or back-illuminated photodiodes, the junction-side commonly being referred to as the front-side. Such back-side illuminated diode arrays are known, and are described in a paper entitled "Development of Low Noise, Back-Side Illuminated Silicon Photodiode Arrays," by S.E. Holland, N.W. Wang, and W.W. Moses published in IEEE Transactions on Nuclear Science Vol.44 No.3 1997.

In the back-side illuminated photodiodes, the (p+)-(n) junction array, which is created on the non-light sensitive

side of the chip, is generally used only for signal readout and therefore can usually be bonded directly to the readout chip or circuitry without obstructing the light from a scintillator. The opposite side (ohmic side) is typically
5   coupled to the scintillator for light detection. This type of array typically operates only in fully depleted mode, which usually requires reverse bias of more than 70 V for the standard 5000 ohm-cm resistivity silicon or higher biases for lower resistivity material.

10   In order to achieve stable I-V characteristic and a low reverse current value, each of the p+ pixels typically incorporates a field plate and surrounding guard rings to optimize the potential distribution around the pixel and to drain out the surface leakage current. These structures
15 typically suffer from the following shortcomings:

    1.   The requirement of high light sensitivity at the ohmic contact conflicts with the technological requirements for effective gettering of the bulk material necessary for maintaining long life times of minority carriers. For
20 effective gettering of the detector bulk, high concentrations of phosphorus dopant and a relatively large thickness of doped material is required in the n+ contact. On the other hand, in order to ensure high light sensitivity, the contact has to be made as thin as possible
25 with an optimized doping profile. Thinning of the contact is at the cost of the gettering process, and it usually causes an increase in the dark leakage current in the constructed arrays;

    2.   In the known back-side illuminated structures, in
30 order to achieve full depletion at low bias voltages and to reduce the bulk generation current component, designers favor the use of very thin wafers. However, this creates

3

technological problems due to the lack of mechanical strength of the thin silicon material;

3.   Reduction of the surface leakage current is usually achieved by constructing a field plate structure at the periphery of individual pixels. However, this is known to lead to generation of defects at the interface between SiO and Si in the field plate. These defects typically are a source of excess reverse current. Some reduction of the defect density can usually be achieved by use of costly high purity processes and materials;

4.   For low leakage operation, the back-side illuminated structures generally require guard ring structures typically surrounding each individual pixel, and at least surrounding small groups (32 to 64) of pixels. These guard ring structures require additional physical space between the pixels and create problems in building high-density arrays or mosaics of such arrays.

SUMMARY OF THE INVENTION

In one embodiment according to the present invention, a detector array is formed on a semiconductor material having a first side and a second side. The detector array includes an entrance window formed on the first side. The entrance window is used to receive radiation. The detector array also includes an array of detectors formed on the second side. One or more of the detectors are used for detecting the radiation received via the entrance window. The entrance window forms a junction with the semiconductor material, and the detectors include pixelated ohmic contacts.

In another embodiment according to the present invention, a method of forming a detector array on a

4

semiconductor material having a first side and a second side is provided. An entrance window is formed on the first side. The entrance window is used for receiving radiation. An array of detectors is formed on the second
5   side. One or more of the detectors are used for detecting the radiation received via the entrance window. The entrance window forms a junction with the semiconductor material, and the detectors include pixelated ohmic contacts.

10   In yet another embodiment of the present invention, a composite detector array includes multiple detector arrays.

In still another embodiment of the present invention, a detector array is formed on a semiconductor material having a first side and a second side. The detector array
15   includes entrance window means formed on the first side. The entrance window means is used for receiving radiation. The detector array also includes an array of detector means formed on the second side. One or more of the detector means are used for detecting the radiation received via the
20   entrance window means. The entrance window means form a junction with the semiconductor material, and the detector means include pixelated ohmic contacts.

BRIEF DESCRIPTION OF THE DRAWINGS
25   The above and other features of the present invention may be more fully understood from the following detailed description, taken together with the accompanying drawings, wherein similar reference characters refer to similar elements throughout and in which:

30   FIG. 1 is a cross-sectional view of a detector array produced from high resistivity n-type Si (top) and back-

side view (bottom) in an embodiment according to the present invention;

FIG. 2 is a cross-sectional view of a detector array produced from high resistivity p-type Si (top) and back-side view (bottom) in an embodiment according to the present invention;

FIG. 3 is a cross-sectional view of an avalanche detector constructed from high resistivity n-type Si in an embodiment according to the present invention;

FIG. 4 is a top view of the topology of a detector array showing separate grids for changing of the pixel sizes by biasing appropriate grids in an embodiment according to the present invention;

FIG. 5 is a top view illustrating the method for joint biasing of individual grid arrangements by coupling grids together; and

FIG. 6 is a top view illustrating the method for individually biasing the grid arrangements.

DETAILED DESCRIPTION

In one embodiment of the present invention, a new junction-side illuminated silicon detector array of pixelated silicon detectors and a method of constructing the same are disclosed. The detectors may be constructed from high resistivity silicon (Si) with a common junction contact on the front-side and ohmic contacts implemented as a pixelated array on the back-side.

In the present invention, the junction contact preferably covers the entire detector array and serves as a front-side light, x-ray, gamma ray and/or particle sensitive window without dead areas. To isolate the individual ohmic contact pixels on the back-side, the

6

inter-pixel gaps preferably contain junction separation implants that surround each pixel in the form of a grid or rings created on the entire array. In this way, the light entrance contact of the present invention may be improved

5 in terms of depth and profile for better light sensitivity.

The entrance window of the present invention preferably allows for better gettering of the bulk material than in the back-side illuminated method, thus allowing for reduction of bulk generated current. In addition, the

10 operational bias of the present invention may be up to four times lower than required for the traditional back-side illuminated structures. Using the structure in an embodiment according to the present invention, the field plates may be eliminated, resulting in decrease of the

15 excess current, and the guard-ring structures may be eliminated, reducing the gap between pixels, and thus allowing for construction of high-density arrays.

The photodetector array construction of the present invention may have significant advantages in the mass

20 production process due to lower operating bias voltages, significantly simplified testing, use of thicker Si wafers (less breakage during processing), and possible very high production yields. Use of thicker wafers opens up additional possibilities of processing 6" (instead of 4"

25 or even larger diameter wafers leading to the possibility of further reduction in production costs.

The photodetector arrays of the present invention may have one or more of the following advantages over the conventional devices:

30 1) The light entrance contact may be formed by boron implantation or other doping methods such as diffusion of

7

deposited dopants and may be improved in terms of depth and profile for better light sensitivity;

2) The technology of photosensitive contacts does not interfere substantially with the requirements of the improved gettering of the bulk material that allows reduction of the bulk generated current;

3) The operational bias may be up to four times lower than required for the traditional back-side illuminated structures;

4) The field plates, the guard ring structures, and associated excess current may be eliminated;

5) Construction of pixels without using guard rings may allow reducing the gap between pixels and may make the high-density arrays feasible;

6) Testing of the proposed structures may be significantly simplified compared to the traditional designs; and

7) The lower bias voltages combined with simpler and more optimized technology may lead to the significant improvement in production yields.

The detector array of the present invention may also be used as a radiation hardened detector for high-energy physics research for detection of particles, x-ray, or gamma rays. The radiation hardness of this structure may be achieved through simplified construction (lack of the field plates and excessive guard rings) and relatively low operating bias voltages. The present invention may also find other broad applications including, but not limited to, applications as novel designs for avalanche imaging arrays (photodetectors with an internal gain).

The signals may be coupled from the pixelated ohmic contacts in the present invention to the readout

8

electronics. Because the readout is done on the opposite side of the entrance window on the silicon wafer, it is possible to couple the device to a scintillator, a scintillator array, a light guide or a diffuser placed

5 directly on the entrance window without interfering with the connections to the readout electronics.

Current silicon processing equipment for this technology usually limits the size of a detector wafer to approximately 10 cm to 20 cm in diameter. In order to make

10 a detector with larger dimensions, it typically is necessary to create modules on the wafers and cut them out for further assembly. The individual modules can then be tiled together into larger arrays. The basic structures according to the present invention may be built in form of

15 modules with a minimum dead space at the edges.

Detector arrays of the present invention may be coupled to CsI(Tl) scintillator arrays in various manners to achieve a seamless boundary between modules. One method may include making smaller photodetector pixels at the

20 detector periphery to compensate for the excess material outside of the active part of the device. The scintillator pixels maintain a uniform size and pitch across boundaries of the photodetector modules. Another method may include sharing of light from common scintillation pixels.

25 The detector array (e.g., at an entrance window) may be directly coupled with the CsI(Tl) scintillator. The detector array may also be coupled with the CsI(Tl) scintillator via an interface that functions as a light guide between the entrance window and the CsI(Tl)

30 scintillator. The interface may include a diffuser to spread the light coming out of the scintillator and may comprise glass, plastic, gel, grease and/or any other

suitable material. The interface may also be used to perform index of refraction matching between the silicon detector (or silicon oxide or other entrance material on the detector) and the scintillator. It may further be used

5 to match non-flat surfaces of the scintillator and the entrance window.

The low cost and high yields of the structures in embodiments according to the present invention coupled to CsI(Tl) scintillating crystals may allow for construction

10 of large-sized solid state gamma cameras and systems for Single Photon Emission Computed Tomography (SPECT) with superior performance and low cost.

Referring now to the drawings and in particular to FIG. 1, a light sensitive array 10 in an embodiment

15 according to the present invention is constructed from n-type silicon (Si) 14. The n-type Si 14 preferably is high resistivity Si, such resistivity preferably being between 1000 ohm-cm to 20,000 ohm-cm. The light sensitive array 10 has a common p^+ light sensitive contact 20 on the front-side

20 and ohmic contacts implemented as a n^+ pixelated array 24 on the back-side. The n^+ pixels on the back-side preferably are coupled to readout electronics via pre-amplifiers (not shown).

The p^+ light sensitive contact preferably covers the

25 entire light sensitive array 10 and serves as a light sensitive window with substantially no dead areas. The p^+ light sensitive contact 20 may also be referred to as an entrance window contact or as an entrance window. An electrically insulating layer 22, which may include SiO_2,

30 surrounds the entrance window on the front-side of the light sensitive array 10.

To isolate the individual n' pixels 24, the inter-pixel gap contains p' separation implants 26 that surround each pixel in the form of a p' grid 28 created on the entire array. In other embodiments, the p' implants may form a

5 number of p+ rings to isolate the individual n' pixels 24. The p+ grid or the p+ rings may be created on separate parts of the array, which may then be connected together externally, or they may be placed directly on the entire silicon array.

10 A reverse bias preferably is applied between the n' pixels 24 and the p' light sensitive contact 20 and between the n' pixels 24 and the p' grid 28. The value of an operational bias voltage $-V_R$ 34 applied to the p' light sensitive contact 20 and the grid voltage $-V_G$ 36 applied to

15 the p' grid 28 may be different and should ensure pinch off 30 between a front depleted region 32 extending from the front contact toward the bulk of the substrate and a pixel depleted region 33 extending from the pixels towards the bulk material. For example, V_R may range from -1 to -10 V

20 (depending on substrate resistivity) and V_G may range from -10 to -200 V (depending on substrate resistivity and thickness). The pinch off 30 between these two depleted regions is a condition for proper pixel isolation. Before the pinch off occurs, the light sensitive array 10 operates

25 as a single photodiode.

The operational bias voltage, $-V_R$ 34 applied to the p' light sensitive contact 20 may be lower by up to a factor of four than the bias voltage necessary to operate standard back-side illuminated silicon structures fabricated from

30 identical starting materials. During testing of the light sensitive array 10, it is not required to measure each of the (thousands of) individual pixels at a great expenditure

11

of time and resources. Instead, a complete evaluation of the array may be achieved with only two measurements. The first measurement is of the leakage current of the fully biased p$^+$ light sensitive contact 20 (without biasing the p$^+$ grid 28). The second measurement is of the leakage current of the fully biased p$^+$ grid 28 (without biasing the p$^+$ light sensitive contact 20). Measured values of the leakage currents less than 10 nA/cm^2 for the p$^+$ light sensitive contact 20 and p$^+$ grid 28 may be an indication of the proper operation of the entire light sensitive array 10. Leakage currents as low as 100pA/cm^2 may be encountered during these measurements.

FIG. 2 is a block diagram of a light sensitive array 100 in another embodiment according to the present invention. The light sensitive array 110 is constructed from p-type Si 114. The p-type Si 114 preferably is high resistivity Si. The light sensitive array 110 has a common n$^+$ light sensitive contact 120 on the front-side and ohmic contacts implemented as a p$^+$ pixelated array 124 on the back-side. The P$^+$ pixels on the back-side preferably are coupled to readout electronics via pre-amplifiers (not shown).

The n$^+$ light sensitive contact 120 preferably covers the entire light sensitive array 110 and serves as a light sensitive window without dead areas. The n$^+$ light sensitive contact 120 may also be referred to as an entrance window contact or as an entrance window. An electrically insulating layer 122, which may include SiO$_2$, surrounds the entrance window on the front-side of the light sensitive array 10.

To isolate the individual p$^+$ pixels 124, the inter-pixel gap contains n$^+$ separation implants 126 that surround

12

each pixel in the form of an n' grid 128 created on the entire array. In other embodiments, the n' implants may form a number of n' rings to isolate the individual p' pixels 124. The n' grid or the n' rings may be created on
5 separate parts of the array, which may then be connected together externally, or they may be placed directly on the entire silicon array.

A reverse bias preferably is applied between the p' pixels 124 and the n' light sensitive contact 120 and
10 between the p' pixels 124 and the n' grid 128. The value of an operational bias voltage +V₁ 134 applied to the n' light sensitive contact 120 and the voltage +V₂ 136 applied to the n' grid 128 may be different and should ensure pinch off 130 between front and pixel depleted regions 132 and 133. The
15 pinch off 130 between these two depleted regions is a condition for proper pixel isolation. Before the pinch off occurs, the light sensitive array 110 operates as a single photodiode.

The operational bias voltage, +V₁ 134 applied to the n'
20 light sensitive contact 120 may be lower by up to a factor of four than the bias voltage necessary to operate standard back-side illuminated silicon structures fabricated from identical starting materials. During testing of the light sensitive array 110, it is not required to measure each of
25 the (thousands of) individual pixels at a great expenditure of time and resources. Instead, a complete evaluation of the array may be achieved with only two measurements. The first measurement is of the leakage current of the fully biased n' light sensitive contact 120 (without biasing the
30 n' grid 128). The second measurement is of the leakage current of the fully biased n' grid 128 (without biasing the n' light sensitive contact 120). Measured values of the

leakage currents less than 10 nA/cm for the n⁺ light sensitive contact 120 and n⁺ grid 128 may be an indication of the proper operation of the entire light sensitive array 110. Leakage currents as low as 100pA/cm may be

5   encountered during these measurements.

FIG. 3 is a block diagram of a light sensitive array (detector array) 12 according to one embodiment of the present invention. The light sensitive array 12 is constructed from n-type Si 14. The n-type Si 14 preferably

10   is high resistivity Si such resistivity preferably being between 1000 ohm-cm to 20,000 ohm-cm. The light sensitive array 12 has a common p⁺ junction electrode 20 on the front-side and ohmic contacts implemented as an n⁺ pixelated array 24 on the back-side.

15   The light sensitive array 12 is similar to the light sensitive array 10 of FIG. 1 in that the light sensitive array 12 preferably is biased at the p⁺ junction electrode 20 and the p⁺ grid 28. In other embodiments, the p⁺ grid 28 may not be biased. Instead, the front depletion region 32

20   may extend down to the p⁺ grid 28.

The p⁺ junction contact 20, which preferably covers the entire light sensitive array 12, preferably is biased at a sufficiently high voltage V_{av} 38 to achieve a controlled avalanche effect (amplification through electron impact

25   ionization). The p⁺ junction contact 20 may also be referred to as an entrance window contact or as an entrance window.

To isolate the individual n⁺ pixels 24, the inter pixel gap contains p⁺ separation implants 26 that surround each

30   pixel in the form of p⁺ rings and/or a p⁺ grid 28 created on the entire array. In the case of avalanche detector arrays, the electric field at the periphery 40 of the p+

junction contact 20 should be shaped in a particular manner so as to prevent premature surface breakdown.

This electric field shape may be achieved through an implementation of a beveled edge structure in the n-type Si

5   14. The bevel may be formed by removing n-type Si material from the edge of the light sensitive array 12 as represented by the broken lines 42, which form a right triangle with the cross-sectional edge of the n-type Si 14. The hypotenuses of the right triangles formed on the left

10   and right sides of the n-type Si 14 indicate the slope of the bevel. The required shaping of the electric field at the periphery 40 may also be achieved through the use of guard rings and/or field plates.

In other embodiments, a p-type silicon may be used to

15   implement a light sensitive array similar to the light sensitive array 12.   In the light sensitive array implemented using the p-type silicon, the entrance window would be implemented with n⁺ junction contact, the pixelated array would include p⁺ pixels, and a grid on the back-side

20   would be implemented using n⁺ implants.

The p+ grid implants 26 forming the grid pattern 23 in the present invention for a n-type substrate, and n+ grid implants 126 forming the grid pattern 123 in the present invention for a p-type substrate may be designed in a

25   variety of ways including, but not limited to, possibility of separation of different sections of the grid with independent biasing or floating of their sections.

Fig. 4 shows a construction of a grid pattern where high resistivity n-type Si 14 is used as the starting

30   material. The readout side of a device 50 in this case includes at least two grid patterns.   One of the grid patterns 52 surrounds a second (interior) set of grid

15

patterns 54. In this case, it is possible to achieve one pixel size by biasing the exterior sections of the grid 52 using voltage V_1, and to change the size of the pixels by biasing the interior sections of the grid 54 using voltage

5 V_1. Using this method, the pixel size and the resulting spatial resolution of the detector array may be electronically regulated.

Referring now to Figure 5, the individual interior grid arrangements 54 may be jointly biased by a single

10 externally applied voltage using V_2 if the individual grids are coupled via a conductive bridge 60 placed over an electrical insulation layer 62 which electrically isolates the interior grid 54 from the exterior grid 52. This may be implemented as a part of planar silicon device

15 fabrication using standard photolithography tools, or after the wafers have been processed on individual detectors using physical masks to define areas for insulator and metal evaporations. Referring now to Fig. 6, the interior grids such as 54 and 56 may be individually biased through

20 external connections to each such grid using voltages V 54, V 56, and the like.

Although the present invention has been described in certain specific embodiments, many additional modifications and variations would be apparent to those skilled in the

25 art. It is therefore to be understood that the present invention may be practiced otherwise than as specifically described. Thus, the described embodiments of the present invention should be considered in all respects as illustrative and not restrictive, the scope of the

30 invention to be determined by the appended claims and their equivalents.
